9

10   **Abstract**

11

12   Black soldier fly (*Hermetia illucens*) meal is a potential alternative to fishmeal and plant proteins in diets for

13   farmed fish since it can be produced on organic waste substrates, requires little energy and water inputs and

14   contains high levels of essential amino acids. Recent studies have partially replaced fishmeal with black soldier

15   fly meal, however, research on their impact on gut microbiota of fish is limited. In a five week experiment, juvenile

16   rainbow trout (*Oncorhynchus mykiss*) were fed either a reference diet based on fishmeal or three diets with 30%

17   inclusion of black soldier fly meals in the form of pre-pupae, larvae or defatted-larvae. The combined luminal

18   content and mucosa were collected from the distal intestine of three fish per tank with four tanks per diet (n=12)

19   and 16S rRNA gene amplicons were sequenced using the Illumina MiSeq platform. Feeding the insect-based diets

20   increased the alpha-diversity of bacteria and abundance of lactic acid bacteria, which may be due to the addition

21   of dietary chitin. Compared with fishmeal, feeding insects resulted in higher abundance of phyla Firmicutes and

22   Actinobacteria with lower abundance of Proteobacteria. Fish fed the full-fat meals had higher abundance of

23   *Corynebacterium* that was attributed to its ability to produce lipase and the high content of dietary lipids as a

24   substrate. Bacillaceae was increased in fish fed both larvae diets and unchanged in the pre-pupae diet, which

25   indicated that life-cycle stage of the insect influenced the gut microbiota. Based on these results, we found that

26   feeding black soldier flies increased diversity and altered the composition of gut bacteria of rainbow trout, which

27   were further influenced by life-cycle stage and lipid content of the insect meal.

28

29   **Keywords**

30   Bacterial diversity; Aquaculture; Distal intestine; Fishmeal replacement; Illumina; Insect meal

Highlights

- Gut bacteria of rainbow trout fed black soldier fly meals were identified using high-throughput sequencing for the first time.

- Feeding larvae, pupae and defatted larval meals resulted in three different gut bacteria profiles, indicating that insect life stage and lipid content are decisive factors influencing the gut microbiota in rainbow trout.

- All three insect diets increased bacterial diversity and lactic acid bacteria that may indicate improved gut health of rainbow trout.

1. Introduction

Aquaculture will require more feed resources to produce more fish for a growing human population. Fishmeal and soy are common protein sources in aqua-feeds, but depleted ocean stocks and demand for human consumption has resulted in higher prices and reduced availability of these ingredients (Tacon, Metian, 2008). Low human-interest alternatives that require less water, land and energy resources are needed. A possible alternative is insects since they can convert organic waste substrates with high efficiency, contain high levels of protein and lipids, require low resource inputs for farming, produce low amounts of greenhouse gases and have relatively low interest from human consumers (Henry, et al., 2015; Van Huis, et al., 2013). Insects are a natural part of the diet for wild fish, especially those inhabiting coastal and inland water-bodies (Whitley, Bollens, 2014). Previous studies have found that rainbow trout (*Oncorhynchus mykiss*) fed fat-enriched black soldier fly pre-pupae can replace 25 and 50% of fishmeal without compromising growth performance (Sealey, et al., 2011; St-Hilaire, et al., 2007). Diets with 50% replacement of fishmeal with black soldier fly defatted-larvae have also resulted in similar growth performance, body indices and gut morphology of rainbow trout compared with fish fed the control diet (Renna, et al., 2017). In addition, replacement of 20-85% of fishmeal with black soldier fly has had no negative effects on growth and feed efficiency of Atlantic salmon (*Salmo salar*) (Belghit, et al., 2018; Lock, et al., 2016), turbot (*Psetta maxima*) (Kroeckel, et al., 2012), European seabass (*Dicentrarchus labrax*) (Magalhães, et al., 2017), barramundi (*Lates calcarifer*), Nile tilapia (*Oreochromis niloticus*) (Muin, et al., 2017) and yellow

2

61 catfish (*Pelteobagrus fulvidraco*) (Xiao, et al., 2018). However, the impact of feeding black soldier fly meal on

62 the gut microbiota of fish is not well known.

63

64 The gut microbiota plays an important role in nutrition, immune system and health of fish (Llewellyn, et al., 2014;

65 Wang, et al., 2018) and the feeding with alternative protein sources such as plants, mussels and microbes (i.e.

66 yeast and microalgae) have been shown to alter diversity and abundance of gut bacteria in salmonid fishes (Desai,

67 et al., 2012; Huyben, et al., 2018; Huyben, et al., 2017; Ingerslev, et al., 2014; Lyons, et al., 2017; Michl, et al.,

68 2017; Nyman, et al., 2017). Recently, a study using gel electrophoresis based sequencing method has found that

69 feeding black soldier fly meal to rainbow trout increased diversity of gut microbiota (Bruni, et al., 2018). A few

70 studies have suggested that chitin, a long-chain polymer of N-acetylglucosamine derived from exoskeleton of

71 insects and crustacean shells, acts as a substrate for chitinase producing bacteria that are not commonly found in

72 the fish gut (Askarian, et al., 2012; Bruni, et al., 2018; Ringø, et al., 2012). Similarly, feeding krill-based chitin

73 has been found to alter the gut microbiota of Atlantic salmon (Askarian, et al., 2012) and Atlantic cod (Zhou, et

74 al., 2013). Rearing substrate, life-cycle stage and lipid content of insects have also been suspected of influencing

75 gut microbiota (Lock, et al., 2016; Sealey, et al., 2011; Xiao, et al., 2018). New advancements in high-throughput

76 sequencing will allow us to identify specific effects of feeding black soldier fly meals on gut microbiota of farmed

77 fish.

78

79 The objective of this study was to investigate the effects of feeding three different black soldier fly meals on the

80 gut microbiota of rainbow trout. Specifically, differences between insect life cycle stage (i.e. larval and pre-pupae

81 meals) and lipid content (i.e. commercial defatted-larvae meal) on the abundance and diversity of bacteria in the

82 distal intestine were investigated using high-throughput 16S rRNA gene amplicon sequencing on the Illumina

83 MiSeq platform.

84

85 **2. Materials and methods**

86

87 *2.1 Fish and facilities*

88

89 The study was performed in the Aquatic Facility of the Centre for Veterinary Medicine and Animal Science at the

90 Swedish University of Agricultural Sciences (SLU; Uppsala, Sweden). Rainbow trout (201.8 ± 13.9 g; mean ±

standard deviation) were acquired from a commercial producer (Vilstena fiskodling AB, Fjärdhundra, Sweden) and housed indoors in 500 L flow-through tanks. Two weeks before the experiment, 160 fish in total were randomly distributed in each of the 16 experimental tanks (10 fish per tank). The fish were acclimatised to a 12 hr light cycle and fed a commercial diet (3 mm, Efico Alpha 714, BioMar A/S, Brande, Denmark). The flow-through system supplied each 200 L oval, fibreglass tank with municipal freshwater at a rate of 6 L min^{-1}. Water was analysed on a weekly basis for temperature (10.9 ± 0.4 °C) and dissolved oxygen (8.8 ± 0.3 mg L^{-1}) using a portable probe (Hach Lange GmbH, Berlin, Germany) and pH (7.3 ± 0.2) using a pH/redox probe (Oxyguard A/S, Farum, Denmark). At the experimental start, fish were sedated with tricaine methanesulphonate (MS-222; 50 mg L^{-1}) buffered with sodium bicarbonate and weighed. The study was performed in compliance with laws and regulations on the use of animals for research purposes in Sweden, which is overseen by the Swedish Board of Agriculture.

2.2 Diets and feeding

Fish were fed either a fishmeal-based reference diet or one of three test diets where the reference diet was mixed in a ratio of 70:30 with a test ingredient of either pre-pupae, larvae or defatted-larvae meal from black soldier fly, as according to Cho (1979). See Table 1 for the formulation of the reference diet. The larvae and pre-pupae meals were produced by the Environmental Engineering Unit, Department of Energy and Technology, SLU (Uppsala, Sweden) as according to Lalander, et al. (2015), except the rearing substrate was based on food compost from a local restaurant. The defatted-larvae meal was produced by a commercial company (Protix, Dongen, The Netherlands) using a wheat bran substrate. The reference diet was first produced by adding the non-test ingredients, listed in Table 1, in a rotating drum mixer and then, separately, 70:30 of the reference diet was mixed with each test ingredient. Gelatin and hot water were added to each diet as a binder, mixed in a kitchen mixer and pressed through a meat grinder that had a 3.5 mm die (Nima Maskinteknik AB, Örebro, Sweden). Diet strings were air-dried at 55 °C for 24 hr, cut into pellets with a kitchen blender (Kneubühler, Luzern, Germany) and stored at -20 °C until the start of the experiment.

For proximate composition of diets (Table 1), dry matter was analysed after treatment at 103 °C for 16 h and ash was determined after treatment at 550 °C for 3 h followed by cooling and weighing (AOAC, 1995). Total nitrogen (N) was determined using a 2020 Digestor and 2400 Kjeltec Analyser (FOSS Analytical A/S, Hilleröd, Denmark)

121   and crude protein (CP) was calculated as N × 6.25 (Nordic Committee on Food Analysis, 1976). Crude lipid was

122   determined using a Soxtec System HT 1043 Extraction Unit (FOSS Analytical A/S, Hilleröd, Denmark) according

123   to the manufacturer (ANKOM Technology, Macedon, NY, USA). Neutral detergent fibre (NDF) was determined

124   according to the Amylase Neutral Detergent method (Mertens, 2002). Acid detergent fibre (ADF) was determined

125   after 1 h boiling in a solution of 0.5 M sulphuric acid and 2% cetyl trimethylammonium bromide according to

126   Method 973.18 of AOAC (AOAC, 1995). Chitin was estimated based on the level of ADF solely derived from

127   the 30% inclusion of the insect meals. Chitin was estimated by subtracting the ADF in 70% of the fishmeal

128   reference diet (i.e. 32.4 g/kg; assumed to be cellulose) from the total ADF in the insect-based diets (Finke, 2007).

129

130   Over the period of five weeks, fish were fed daily at a rate of 1% body weight (BW) per day via automatic belt

131   feeders (Hølland teknologi, Sandnes, Norway) from 10:00 to 12:00. The four diets were randomly assigned to

132   each of the 16 tanks. Feed waste was collected continuously using a belt collector (Hølland teknologi, Sandnes,

133   Norway), weighed twice per day and then pooled for subsequent dry matter analysis. Feed waste was subtracted

134   from the total feed intake using the recovery method according to Helland, et al. (1996).

135

136   *2.3 Sampling of the distal intestine*

137

138   Fish were fed until terminal sampling on the final day of the study (i.e. within 20-24 hours of final feeding). Three

139   fish from each tank (n=12) were euthanised with an overdose of 200 mg L^{-1} MS-222 buffered with sodium

140   bicarbonate and their cervical vertebrae were severed. Under sterile conditions, the midline of each fish was

141   dissected near a flame within a fume hood and the distal intestine (hindgut) was cut and removed between the

142   ileorectal valve and 0.5 cm before the anal opening. The intestine was cut longitudinally and a scalpel was used

143   to scrape and collect 200-400 mg of luminal content and mucosa (combined) into a sterile Eppendorf tube

144   containing 1mL of RNAlater® (Sigma-Aldrich Co, St. Louis, MO, USA). Samples were kept on ice for less than

145   six hours and then stored at -80 °C until later analysis. Both luminal content and mucosa were collected and

146   analysed together in order to show a comprehensive representation of both allochthonous (transient) and

147   autochthonous (adhered) bacteria in the distal intestine.

148

149   *2.4 Preparation for 16S rRNA gene sequencing*

150

151   DNA was isolated from intestinal samples and 16S rRNA gene amplicons were generated using a two-step PCR

152   with meta-barcoding. The amplicons were purified with magnetic beads, pooled into a single library and

153   sequenced using an Illumina MiSeq platform, according to Herlemann, et al. (2011) and Hugerth, et al. (2014)

154   with modification by Huyben, et al. (2017). In brief, approximately 200 mg of intestinal content/mucosa in

155   RNAlater® solution were transferred to sterile tubes containing 0.5 g of 0.1 mm silica beads and homogenised in

156   a Precellys homogeniser (Bertin Instruments, Montigny-le-Bretonneux, France) for two cycles of 60 sec at 6000

157   rpm followed by 5 min rest on ice. The DNA was extracted using a QIAamp Fast DNA Stool Mini Kit (Qiagen

158   Gmbh, Hilden, Germany) according to the manufacturer's instructions. Amplicons were prepared by adding 2 μL

159   of template DNA to sterile tubes containing 1 μL of each primer (10 μM), 8.5 μL nuclease-free water and 12.5

160   μL of 2x concentrated Phusion® High-Fidelity Master Mix (Thermo Fisher Scientific Inc., Waltham, MA, USA).

161   The V4 region of the 16S ribosomal RNA gene was amplified using the primers 515F (5'-

162   GTGCCAGCMGCCGCGGTAA-3') and 805R (5'-GACTACHVGGGTATCTAATCC-3') (Hugerth, et al.,

163   2014). Conditions for PCR included denaturation at 98 °C for 30 sec, followed by 35 cycles of 98 °C for 10 sec,

164   60 °C for 30 sec and 72 °C for 10 sec, ending with 72 °C for 2 min. Amplicons were visualised by gel

165   electrophoresis and purified using Agencourt AMPure XP magnetic beads according to the manufacturer's

166   instructions (Beckman Coulter Inc., Bromma, Sweden). The 515F and 805R primers containing Illumina-

167   compatible barcodes (eight nucleotide combinations) with adapters were used to tag each sample individually

168   during the second PCR step. Amplicons of 10.5 μL were added to sterile tubes containing 1 μL of each barcode

169   primer (10μM) and 12.5 μL of 2x concentrated Phusion® High-Fidelity Master Mix (Thermo Fisher Scientific

170   Inc). Conditions for the second PCR step included denaturation at 98 °C for 30 sec, followed by 10 cycles of

171   denaturation at 98 °C for 10 sec, hybridisation at 62 °C for 30 sec and elongation at 72 °C for 5 sec, followed by

172   final elongation at 72 °C for 2 min. The amplicons were purified as before, quantified using a Qubit® 3.0

173   Fluorometer (Invitrogen, Thermo Fisher Scientific), diluted with elution buffer to 10 nM and then all samples

174   were pooled. The pooled library was quality checked (size and abundance) using qPCR and sequenced using the

175   Illumina MiSeq platform at SciLifeLab AB (Stockholm, Sweden).

176

177   *2.5 Bioinformatic analysis of sequence data*

178

179   The bacterial sequence data were processed according to Müller, et al. (2016). In brief, the paired end sequence

180   reads were quality trimmed using the Cutadapt tool (Martin, 2011) in Python version 2.7 (Python Software

181   Foundation, http://www.python.org) to remove remaining adaptor and primer sequences, bases with quality below

182   10 from the 3' end, reads containing N bases, reads longer than 300 base pairs and reads not containing primer

183   sequences. Paired end reads were joined using the join_paired_ends.py function according to the SeqPrep method

184   (https://github.com/jstjohn/SeqPrep) in Quantitative Insights into Microbial Ecology (QIIME) version 1.8.0

185   (Caporaso, et al., 2010b). The joined reads were then used for split libraries and the operational taxonomic units

186   (OTUs) were assigned using the open reference OTU picking strategy at a threshold of 97%, using U-CLUST

187   against Greengenes core set (gg_13_8) (Edgar, 2010; Rideout, et al., 2014). The representative sequences were

188   aligned against the Greengenes core set using PyNAST software (Caporaso, et al., 2010a). The chimeric sequences

189   were removed by ChimeraSlayer (Haas, et al., 2011). Taxonomy was assigned to each OTU using the Ribosomal

190   Database Project (RDP) classifier with a minimum confidence threshold of 80% (Wang, et al., 2007). The

191   alignment was filtered to remove gaps and hypervariable regions using a Lane mask and a maximum-likelihood

192   tree was constructed from the filtered alignment using FastTree (Price, et al., 2010). The final OTU table was

193   further filtered to include OTUs present in at least three samples and to exclude OTUs identified as chloroplasts

194   and mitochondria, since only bacteria were of interest. In addition, the number of reads per sample was normalised

195   (termed subsampled) to equal that in the sample with the lowest number of reads (i.e. 10,238). The 16S rRNA

196   gene sequences were deposited in the NCBI Sequence Read Archive (SRA) as SRA Accession SRP144010 and

197   BioProject PRJNA454155 (https://www.ncbi.nlm.nih.gov/bioproject/PRJNA454155).

198

199   *2.6 Statistical analyses*

200

201   All data were analysed using $R^{©}$ version 3.3.1 (R-Core-Team, 2015) with the 'vegan' (Oksanen, et al., 2018) and

202   'nlme' (Pinheiro, et al., 2014) statistical packages. For α-diversity of bacterial OTUs in the gut, No. of OTUs/taxa,

203   Shannon diversity and Chao-1 richness indices were generated from non-transformed count data using rowSums,

204   diversity and estimateR functions. Significant differences between diets were determined by applying a Linear

205   Mixed Effects (LME) model with diet as a fixed effect and tank as a random effect followed by Least Square

206   Means test (lsmeans package) with Tukey adjustment to account for multiple pair-wise comparisons (Lenth,

207   2016). A value of $p<0.05$ was considered significant.

208

209   For β-diversity, plots of bacterial OTUs were produced based on Non-Metric Multidimensional Scaling (NMDS)

210   with Bray-Curtis index after 2D Wisconsin standardization of square-root transformed data (metaMDS function).

Similarity Percentage Analysis (SIMPER) followed by one way Permutational Multivariate Analysis of Variance (PERMANOVA; adonis function) using Bray-Curtis index at 999 permutations (McArdle, Anderson, 2001; Oksanen, et al., 2018) with diet and tank as factors. Bonferroni adjusted p-values were generated to determine significant differences between diets in terms of composition of gut bacteria. In addition, the LME model and lsmeans test used above were applied to bacterial OTUs at the genus, order and phylum levels that had a mean relative abundance >1% in order to determine effects of each diet on the most prevalent bacterial groups.

3. Results

Illumina Miseq sequencing of the v4 region of the 16S rRNA gene from the gut content/mucosa of rainbow trout fed the fishmeal and insect diets produced a normalised count of 10,238 sequence reads per fish (491,424 in total) that identified to 878 individual OTUs belonging to 109 known taxa (grouped by genus) after data quality filtering. Before filtering and subsampling, the number of sequence reads was $76,875 \pm 3,612$ (mean ± SE) per sample for a total of 3.7 million sequences. Analysis of OTUs showed that alpha-diversity of gut bacteria increased for fish fed all three insect-based diets compared with the fishmeal diet (Table 2). Fish fed the pre-pupae diet showed the highest diversity for all three indices and was significantly higher than fish fed larvae and defatted-larvae diets for the Shannon and Choa-1 indices (Fig. 1). Compared with fishmeal, fish fed the larvae diet had increased Shannon diversity and fish fed the defatted-larvae diet had higher Chao-1 richness.

Diet had an overall effect on the beta-diversity and composition of bacterial OTUs in the gut (PERMANOVA; F=24.132, R^2=0.633, p=0.001), although there was no significant effect of tank (PERMANOVA; F=1.300, R^2=0.126, p=0.161). Composition of gut bacteria was significantly different between fish fed each diet (p<0.01), while least dissimilar between fish fed the larvae and defatted-larvae diets (SIMPER; 71.4%). Compared with fishmeal diet, fish fed the defatted-larvae diet were the most dissimilar followed by fish fed the pre-pupae and larvae diets (SIMPER; 90.3, 87.7 and 82.6%). The NMDS plot (Fig. 2) agreed with the SIMPER analysis as the cluster of fish fed the fishmeal diet were separated from fish fed the insect-based diets, while furthest from the pre-pupae diet.

Relative abundances of bacterial OTUs found in the fish gut were mainly represented by the phyla Firmicutes, Proteobacteria and Actinobacteria (Fig. 3). Compared to fishmeal diet, Firmicutes significantly increased in fish

fed the larvae and defatted-larvae diets (LME, N=12; p=0.002 and <0.001, respectively), Actinobacteria increased

in fish fed the pre-pupae and larvae diets (p<0.001 and 0.009, respectively) and Proteobacteria decreased for all

the insect-based diets (p=0.002, 0.003 and 0.001, respectively). On the order level, most OTUs were represented

by Bacillales, Pseudomonadales, Actinomycetales and Lactobacillales (Fig. 4). Compared to fishmeal diet,

Bacillales significantly increased in fish fed the larvae and defatted-larvae diets (p=0.012 and <0.001,

respectively), Pseudomonadales decreased for all the insect-based diets (p=0.005, 0.008 and 0.003, respectively),

Actinomycetales increased for the pre-pupae and larvae diets (p<0.001 and p=0.009, respectively) and

Lactobacillales increased for the pre-pupae and larvae diets (p=0.043 and p<0.001, respectively). On the genus

level, OTUs with >1% relative abundance (by decreasing abundance) included *Corynebacterium, Pseudomonas,*

Photobacterium, Achromobacter, Virgibacillus, Facklamia, Flavobacterium, Lactobacillus, Brevibacterium and

Lactobacilliceae;Other (unclassified). There was a significant effect of diet (p<0.05) on the OTUs with >1%

abundance, except for *Flavobacterium* and *Achromobacter* (p=0.080 and 0.311, respectively). For significant

differences between diets, see Fig. 5.

Fish fed the fishmeal, pre-pupae, larvae and defatted-larvae diets had a mean individual weight gain of 74.0, 74.1,

81.8 and 66.1 g (SE = 8.1 g) , respectively, and a mean individual feed intake of 81.5, 88.2, 89.1 and 77.2 g (SE

= 2.4 g), respectively. No mortalities were recorded during the experiment.

4. Discussion

4.1 Dietary chitin and chitinase producing bacteria

This study is the first to analyse the effects of feeding black soldier fly meals on the gut microbiota of rainbow

trout using high-throughput sequencing (i.e. Illumina next-generation sequencing). This method highlighted the

dramatic shift from high Proteobacteria:Firmicutes ratio in the gut of fish fed fishmeal to a low ratio with increased

bacterial diversity in fish fed the insect-based diets (Fig. 3, Table 2). Chitin may have acted as a new substrate to

increase the proliferation of chitinolytic bacteria, which are mainly represented by the Firmicutes phyla and

include many *Bacillus* species (Cody, 1989). Using Sanger sequencing of agar cultured isolates, *Bacillus* spp.

were found in the intestine of Atlantic salmon fed a diet with 5% chitin and this group of bacteria showed the

highest chitinase activity *in vitro* (Askarian, et al., 2012). Similarly, we found significant increases in Bacillaceae

271 (the family including *Bacillus*) in our study in fish fed diets with black soldier fly larvae as well as defatted-larvae

272 diets. In addition, previous studies have found that feeding with black soldier fly larvae or krill-derived chitin can

273 significantly change the gut microbiota in rainbow trout (Bruni, et al., 2018) and Atlantic cod (Zhou, et al., 2013).

274 Lastly, supplementation of chitinase enzymes derived from bacteria in chitin-based diets has been shown to

275 increase growth performance of hybrid tilapia (Zhang, et al., 2014). The higher dietary chitin in the insect-based

276 diets may explain the significant change in gut microbiota of fish.

277

278 *4.2 Increased bacterial diversity and abundance of lactic acid bacteria*

279

280 High bacterial diversity is considered to have a positive effect on gut health since species-rich communities are

281 thought to out-compete pathogens for nutrients and colonization, consequently resisting pathogen invasion and

282 intestinal infection (Cerezuela, et al., 2013; Levine, D'Antonio, 1999; Yachi, Loreau, 1999). Therefore, fish fed

283 all three insect diets, especially pre-pupae, in our study may have a healthier gut microbiota since their bacterial

284 alpha-diversity was higher compared with the fishmeal diet (Table 2). One possible reason for the highest diversity

285 in fish fed the pre-pupae diet may be a higher content of dietary chitin (Table 1). Previous studies have suggested

286 that more chitin is deposited in the exoskeleton of insects at later life-cycle stages (Xiao, et al., 2018). However,

287 other studies have found similar levels of chitin between life stages, although amino acid composition had changed

288 (Finke, 2007). Chitin is not a typical component in commercial aquafeeds, thus its inclusion may stimulate the

289 colonisation and growth of less common bacteria in the intestine that have the ability to digest chitin as a source

290 of nutrients. In Atlantic salmon, feeding chitin was found to increase lactic acid bacteria (i.e. order of

291 Lactobacillaceae) in the gut as well (Askarian, et al., 2012). Studies have suggested that chitin may be a

292 preferential substrate for lactic acid bacteria in the gut of salmonids (Bruni, et al., 2018), which explains the

293 increased abundance when fish were fed the insect-based diets in the present study (Fig. 4). Increased abundance

294 of lactic acid bacteria has been used as an indicator of a healthy gut since they produce bacteriocins that inhibit

295 pathogens (Dimitroglou, et al., 2011; Merrifield, et al., 2010; Ringø, Gatesoupe, 1998). In addition, several studies

296 have found a decreased abundance of lactic acid bacteria associated with reduced growth or temperature stress in

297 salmonids (Hovda, et al., 2012; Huyben, et al., 2018; Huyben, et al., 2017; Neuman, et al., 2016). However, a

298 recent study found that abundance of lactic acid bacteria increased in Atlantic salmon with soybean meal-induced

299 enteritis (Gajardo, et al., 2017), which challenges this bacterial order as a positive indicator of gut health. The

300 increased bacterial diversity and abundance of lactic acid bacteria indicate that feeding black soldier fly meals

301 may improve gut health of rainbow trout, although further studies are needed to correlate changes in intestinal

302 bacteria with empirical health indicators, e.g. morphology and gene expression.

303

304 *4.3 Effect of dietary lipids and insect rearing conditions on fish gut bacteria*

305

306 The crude lipid content of the insect meals may have altered the gut microbiota in the fish since the full-fat larvae

307 and pre-pupae diets had 71 and 40 g kg^{-1} higher levels than the defatted-larvae diet (Table 1). Insect meal can be

308 defatted in order to reduce the lipid content to maintain feed pellet stability and avoid altering the lipid composition

309 of the fish fillet (Henry, et al., 2015; Sealey, et al., 2011). In our study, OTUs of *Corynebacterium* (including *C.*

310 *variabile*) were significantly higher in fish fed the full-fat larvae and pre-pupae (Fig. 5) and this bacterium has

311 been reported to produce high levels of lipase (Brennan, et al., 2002). The *C. variabile* has been found in the gut

312 of insects, such as the common fruit fly (*Drosophila melanogaster*) (Storelli, et al., 2011) and predatory mites

313 (*Neoseiulus cucumeris*) (Pekas, et al., 2017), which suggests this bacterium in our study may have originated from

314 the insect meal. This bacterium may also be derived from the insect rearing facility or substrate. The *C. variabile*

315 can tolerate pH values below 4.9 (Brennan, et al., 2002), which may have allowed it to bypass acidic conditions

316 in the fish stomach and colonise the intestine. Fish fed the defatted-larvae meal had very low abundance of

317 *Corynebacterium* (i.e. <1%; Fig. 5), which corresponds to the low lipid content in the diet. These results indicate

318 the lipid composition in the diet and/or bacteria present in the insect meals may have influenced the gut microbiota

319 in these fish, although these aspects need further investigation.

320

321

322 The rearing conditions and microbiota of the insects fed to fish may have influenced the gut microbiota of the fish

323 in our study, especially since the diets were produced via cold-pelleting (opposed to extrusion) that avoids

324 extensive heat inactivation of microbes (Huyben, et al., 2017). In a study that used 454 pyro-sequencing, the

325 microbiota of mealworms and grasshoppers were dominated by the Firmicutes phyla, especially lactic acid

326 bacteria (Stoops, et al., 2016), which is similar to the gut bacteria found in our study (Fig. 3 and 4). The farmed

327 mealworm larvae also had a high abundance of Actinobacteria, which was significantly increased in fish fed black

328 soldier fly larvae and pre-pupae in our study, respectively (Fig. 3). Aside from the effects of dietary lipids,

329 differences in gut bacterial composition of fish fed the full-fat and defatted insects may be due to different insect

330 rearing conditions (i.e. substrate of food compost versus wheat bran). Previous studies have found that different

11

331 substrates, such as those enriched with offal trimmings, used to rear black soldier flies can impact growth

332 performance of rainbow trout and Atlantic salmon (Lock, et al., 2016; Sealey, et al., 2011). This may be the case

333 in our study where restaurant compost was used as a substrate to produce black soldier flies included in the larvae

334 and pre-pupae diets compared with a vegetable substrate for the defatted-larvae diet.

335

336 **5. Conclusions**

337

338 This study showed the effects of feeding black soldier flies in different life-cycle stages and lipid content on the

339 intestinal microbiota of rainbow trout using Illumina high-throughput sequencing for the first time. The

340 composition of gut bacteria was different for each diet and the pre-pupae diet was the most dissimilar compared

341 with the fishmeal diet. Feeding insects resulted in elevated bacterial diversity and abundance of lactic acid

342 bacteria, which is a potential indicator of improved gut health. Fish fed the insect-based diets had increased

343 abundance of Firmicutes and Actinobacteria with a reduction in Proteobacteria. Fish fed larvae and pre-pupae

344 diets had increased abundance of *Corynebacterium*, which was attributed to its ability to produce lipase and the

345 high content of dietary lipids. For both larvae diets, abundance of Bacillaceae was significantly increased and this

346 was attributed to their ability to produce chitinase and the high level of dietary chitin. These results indicate that

347 feeding black soldier fly alters the gut microbiota of rainbow trout and insects harvested at different life-cycle

348 stages and/or defatted further influence the bacterial communities.
